

(a) $r = 0.001$, maximum initial LD(b) $r = 0.1$, maximum initial LD(c) $r = 0.001$, no initial LD(d) $r = 0.1$, no initial LD(e) $r = 0.001$, moderate initial LD(f) $r = 0.1$, moderate initial LD

Figure S4. The effects of initial conditions and recombination rates on evolutionary trajectories when the trait is expressed in both sexes and migration is symmetric and very small, $m = 0.001$. Otherwise, this figure is analogous to Figure 3 (in which $m = 0.01$). The graphs in this figure look similar to those in Figure 3. However, often less divergence is maintained at equilibrium compared to $m = 0.01$. Most notably, the time course is about 3–10 times long than with $m = 0.01$. Especially, the trajectories that start with high divergence (red, dark green) hang around very high values of $p_{2,2} > 0.9$ and $t_{2,2} > 0.9$ for very long; typically 1000 generations for the higher recombination rate; and 20,000–50,000 for $r = 0.001$. During this time, only linkage disequilibrium changes (very slowly), and allele frequencies remain almost constant.
